Abstract—In this paper, the UML activity diagrams are first defined graph-theoretically, with an adoption of the concepts of Petri nets tokens. The semantics of activity diagrams is further axiomatized as a logical action theory called SCAD. Example applications of SCAD are also given.

Keywords—UML Activity Diagrams; Situation Calculus Ontology

I. INTRODUCTION

The Unified Modeling Language (UML) activity diagrams are designed for graphical specifications of dynamical aspects of systems. They have been widely used to model work flows of, e.g., business processes and software systems. For each graphical notation of activity diagrams, only a textual description is provided by the Object Management Group (OMG) to define its syntax and semantics [3].

In this paper, we start by providing a graph-theoretic definition for the activity diagrams and formal characterizations of activity diagram dynamics through adopting the concepts of Petri nets tokens. We move on to propose an ontology of activity diagrams called SCAD, standing for Situation-Calculus action theory for Activity Diagram; whereas situation calculus (Reiter’s variety, see [2]) is a second-order logic language that provides a rigorous paradigm for axiomatizations of dynamical systems.

SCAD contains a set of actions, corresponding to the firing of diagram nodes, and a set of function fluents, corresponding to the number of tokens at diagrams nodes, which are subject to change upon firing actions. The paper also covers two example SCAD applications: one, important mathematical properties of activity diagrams are further axiomatized in SCAD. Consequently, we show that the reachability problem is PSPACE-complete in a subclass of SCAD; two, an example diagram is presented, where the projection problem is investigated in particular.

II. UML ACTIVITY DIAGRAMS

In this section, graph-theoretic definitions to describe UML activity diagrams are introduced first, and the concept of markings to capture the dynamics of activity diagrams are presented next.

Definition 1: An UML activity diagram is a pair \((N,E)\), where \(N\) is a finite set and \(E\) is a binary relation on \(N\). The elements in \(N\) are called nodes. Each node belongs to one and only one of the following types: Ini, Final, Branch, Merge, Fork, Join, or Action. The elements in \(E\) are called edges. The edge set \(E\) consists of ordered pairs of nodes. That is, an edge is a set \(\{u,v\}\), where \(u,v \in N\) and \(u \neq v\). By convention, we use the notation \((u,v)\) for an edge, rather than the set notation \(\{u,v\}\).

If \((u,v)\) is an edge in an activity diagram, we say that \((u,v)\) is incident from or leaves node \(u\) and is incident to or enters node \(v\). Given a node \(u \in N\), the set \(\star u = \{v| (v,u) \in E\}\) is the pre-set of \(u\), where each \(v\) is the input of \(u\), and the set \(u^* = \{v| (v,u) \in E\}\) is the post-set of \(u\), where each \(v\) is the output of \(u\). It is required that \(^1\)

\[
\begin{align*}
|\star u| &= 0 \quad \text{if } n \text{ is the Ini node} \\
|\star u| &= 1 \quad \text{if } n \text{ is Branch, Fork, Action, or Final} \\
|\star u| &= 2 \quad \text{if } n \text{ is a Merge, or a Join node}
\end{align*}
\]

\[
\begin{align*}
|u^*| &= 0 \quad \text{if } n \text{ is the Final node} \\
|u^*| &= 1 \quad \text{if } n \text{ is Merge,Join, Action or Ini} \\
|u^*| &= 2 \quad \text{if } n \text{ is a Branch , or a Fork node}
\end{align*}
\]

The concept of tokens and its firing is adopted from Petri nets. In a Petri-net, nodes of places contain tokens whereas firing of a transition node make changes to the number of tokens in the places that enter, or leave the transition node. As defined below, a node in an activity diagram by itself maintains tokens and can fire as long as it contains at least one token. In addition, the left (or right) input of a Join node accepts left (or right) tokens and, intuitively, one left token and one right token will be counted as a full token for the Join node.

Definition 2: A marking of a diagram \((N,E)\) is a mapping in the form \(MK : N \rightarrow \mathbb{N}\), to indicate the distribution of tokens on the nodes of the diagram; it can be represented as an vector \(MK(n_1), \ldots, MK(n_m)\) where \(n_1, \ldots, n_m\) is

\(^1\)In general, the in-degrees of Merge and Join, and the out-degrees of Branch and Fork, all can be integers greater than 2.
an enumeration of the node set $N$ and for all $i$ such that $1 \leq i \leq m$, $MK(n_i)$ tokens are assigned to node $n_i$.

A node $n$ is marked at the marking $MK$ if $MK(n) > 0$. A marked node $u$ is also enabled and is accepted by every node $v \in u^*$. The firing of an enabled node $u$ at $MK$ leads to the successor marking $MK'$ (Written as $MK \xrightarrow{u} MK'$). More precisely,

1) if $u$ is a Branch node, then for every node $n \in N$,

$$MK'(n) = \begin{cases} MK(n) - 1 & \text{if } n = u \\ \{MK(n) + 1, MK(n)\} & \text{if } n \text{ accepts } u \\ MK(n) & \text{otherwise} \end{cases}$$

and we also have, $\sum_{i \in u^*} MK(n_i) = 1$;

2) if $u$ is a non-Branch node, then for every node $n \in N$,

$$MK'(n) = \begin{cases} MK(n) - 1 & \text{if } n = u \\ MK(n) + 1 & \text{if } n \text{ accepts } u \\ MK(n) & \text{otherwise} \end{cases}$$

In other words, after the firing of $u$, a token is removed from $u$ and a token is added to the only node (if it is of type $Init$, $Action$, $Merge$, $Join$), each node (if $u$ is of type $Fork$), one and only one node (if it is of type $Branch$), in the post-set of $u$. There is no need to fire a node with type $Final$;

3) (Exception of $Join$) if a token fired by $u$ is accepted by the left (right) in-edge of a $Join$ node $n$, then $MK_{left}(n)$ ($MK_{right}(n)$) is increased by 1. $MK_{left}(n) = 1$ and $MK_{right}(n) = 1$ function as one full token at $n$, i.e., $MK(n) = 1$.

The **firing sequence** $\sigma = n_1, ..., n_m$ is a sequence of nodes in $N$. For particular $\sigma$ and $MK$, $\sigma$ is legal at $MK$ if there are marking sequence $MK_0, MK_1, ..., MK_m$ such that $MK = MK_0$, $MK_0 \xrightarrow{\sigma_1} MK_1$, ..., $MK_{m-1} \xrightarrow{\sigma_m} MK_m$ (written as $MK \xrightarrow{\sigma} MK_m$).

The **reachability problem** for an $(N, E, MK_0)$ is to decide, for some marking $MK'$, if there exists a firing sequence $\sigma$ such that $MK_0 \xrightarrow{\sigma} MK'$. An instance $(N, K, MK_0)$ is $k$-bounded if the number of tokens of any node $n \in N$ at any $MK$ in the reachability set is bounded by $k$.

### III. Situation Calculus

The situation calculus is a logical language for representing changes upon actions in a dynamical domain. The language $L$ of situation calculus as stated by [2] is a second-order many-sorted language with equality.

Three disjoint sorts: action, situation, object (for everything else in the specified domain) are included in the language $L$. For example, $rain$ denotes the act of raining, and $putdown(x, y)$ denotes the act of object $x$ put down $y$ on the ground. A situation characterizes a sequence of actions in the domain. The constant situation $S_0$ is to denote the empty sequence of actions, whereas the function symbol $do$ is introduced to construct the term $do(a, s)$, denoting the successor situation after performing action $a$ (such as, in a weather simulation scenario, $rain$) in situation $s$. The situation term $do(sunshine, do(rain, s))$ denotes the situation resulting from first $rain$ and then $sunshine$, which distinguishes itself from the other situation term $do(rain, do(sunshine, s))$. It is easy to see that, intuitively, a situation corresponds to a finite sequence of actions.

The binary predicate $\sqsubseteq$ specifies the order between situations. For example, $s \sqsubseteq s'$ stands for that the situation $s'$ can be reached by performing one or several actions from $s$. $s \sqsubseteq s'$ is an abbreviation of $s \sqsubseteq s' \land s = s'$. In addition, a predicate $Poss(a, s)$ is applied to specify the legality of performing action $a$ in situation $s$. For example, $Poss(rain, s) \sqsubseteq heavyCloudy$ says that it is possible to rain only if the sky is with heavy cloud.

In a particular domain, the language might contain situation independent relations, like $matchLocation(Toronto)$, and situation independent functions, like $size(Plot2)$. However, in many of the more interesting cases, the values of relations and functions change between situations; accordingly, a relational fluent, or a functional fluent, in $L$ is defined as a predicate, or a function, respectively, whose last argument is always a situation (e.g., $captain(John, do(catchFever, S_0))$ is a relational fluent, whereas $weight(John, do(recover, s))$ is a functional fluent).

### IV. SCAD

The ontology of SCAD is formally defined in this section. Aside from situations and actions, objects in SCAD include diagram nodes: $Init$, $Final$, $Action$, $Branch$, $Merge$, $Fork$, and $Join$. Functions of actions in SCAD include

- $fireJ(j)$: firing a $Join$ node;
- $fireB_b$: firing a $Branch$ node to its left edge;
- $fireB_r$: firing a $Branch$ node to its right edge;
- $fire(p)$: firing a node other than $Join$ and $Branch$.

Functional fluents includes:

- $TknsJ_j(j, s)$: the number of left tokens at a $Join$ node $j$ in situation $s$;
- $TknsJ_r(j, s)$: the number of right tokens at a $Join$ node $j$ in situation $s$;
- $Tkns(p, s)$: the number of tokens at a non-$Join$ node $p$ in situation $s$.

Situation-independent relations are defined in $S_{S_0}$ of SCAD, which specifies the structure of an activity diagram and include:

- $LpreL(m, n)$: the left output of a $(Fork$ or $Branch)$ node $m$ enters the left input of a $Merge$ or $Join$ node $n$, $LpreR(m, n)$, $RpreL(m, n)$, and $RpreR(m, n)$ are defined in a similar way;
- $Lpre(m, n)$: the left output of a $(Fork$ or $Branch)$ node $m$ enters the only input of node $n$ that is not of type $Merge$ or $Join$, $Rpre(m, n)$ is defined similarly;
• \(preL(m,n)\): the only output of a (non-Fork and non-Branch) node \(m\) enters the left input of of a type Merge or Join node \(n\), \(preR(m,n)\) is defined similarly;
• \(pre(m,n)\): all cases including the other cases (i.e., the only input of the node \(m\) enters the only input of the node \(n\), and all of the above cases;
• \(post(m,n)\): \(m\) leaves \(n\) if and only if \(n\) enters \(m\).

**Definition 3:** SCAD is defined as a logical theory \(S_{\text{scad}}\), which consists several sets of axioms as follows:

\[
S_{\text{scad}} = D_f \cup S_{\text{ap}} \cup S_{\text{ss}} \cup S_{\text{una}} \cup S_{\text{So}}
\]

where

- \(D_f\) is the foundational axioms (see [2] for details);
- \(S_{\text{ap}}\) (action preconditions axioms)
  - \(\text{Poss}(\text{fire}.J(j),s) \equiv TknkJ(j,s) \geq 1 \land TknkJ(r,j,s) \geq 1\) (a Join node \(j\) is enabled to fire iff the number of left tokens and the number of right tokens of it, both are greater than, or equal to 1);
  - \(\text{Poss}(\text{fire}.B_i(b),s) \equiv TknkB_i(b,s) \geq 1\) (a Branch node \(b\) is enabled to fire to its left iff the number of tokens it contains is greater than or equals to 1);
  - \(\text{Poss}(\text{fire}.B_r(b),s) \equiv TknkB_r(b,s) \geq 1\) (a Branch node \(b\) is enabled to fire to its right iff the number of tokens it contains is greater than or equals to 1);
  - \(\text{Poss}(\text{fire}.p,s) \equiv Tknk(p,s) \geq 1\) (a node \(p\) is enabled to fire iff the number of tokens it contains is greater than or equals to 1);
- \(S_{\text{ss}}\) (successor state axioms)
  - \(\text{Tknks}(p,do(a,s)) = n \equiv \gamma_f(p,t,n,a,s)\land \neg \exists n' \gamma_f(p,t,n',a,s)\) (at situation \(s\), the number of tokens of the node \(p\), which is of type Join, is \((n-1)\), and \(p\) fires at situation \(s\), making the number of tokens at the subsequent situation \(do(a,s)\) also to \(n\));
  - \(\text{Tknks}(p,do(a,s)) = n \equiv \gamma_f(p,t,n,a,s)\lor \neg \exists n' \gamma_f(p,t,n',a,s)\) (at situation \(s\), the number of tokens at place \(p\), which is of type Fork, is \((n+1)\), and \(p\) fires at situation \(s\), making the number of tokens at the left edges of place \(p\), fires at \(s\), and \(p\) fires at situation \(s\), making the number of tokens at the right edges of place \(p\), fires at \(s\), and \(p\) fires at situation \(s\), making the number of tokens at the subsequent situation \(do(a,s)\) also to \(n)\);
- \(\text{K-boundedness}\)
Figure 1. An activity diagram

In [4], it is shown that the reachability problem in a general K-bounded activity diagram is PSPACE-complete, that is, given a SCAD action theory \( S_{scad} \), deciding
\[
S_{scad} \cup Q_{kbound}(s, p) \models Q_{reach}(s, p)
\]
is PSPACE-complete; whereas the problem is NP-Complete if one further constraint (namely reversibility) is added.

Here we show in addition that

**Theorem 1:** Given an \( S_{scad} \) where its nodes are free of Branch and Merge types, deciding
\[
S'_{scad} \cup Q_{kbound}(s, p) \models Q_{reach}(s, p)
\]
is PSPACE-complete.

**Proof:** (Sketch.) The same nondeterministic algorithm for the general case appeared in [4] can still be applied here to show that the problem is in PSPACE.

To show that it is PSPACE-hard, we transform the PSPACE-complete Deterministic Linear Space Acceptance (DLSA) problem (see [1]) into the current problem. The proof is similar to the PSPACE-hard proof for Theorem 1 in [4], where a PSPACE-complete nondeterministic Linear Space Acceptance (NLSA) problem is applied. Here the transition function is easier as no Branch node is needed. In case a node belongs to multiple components, instead of using Merge, Branch nodes and poly-bounded duplicates of the nodes are introduced, and the proof then can be carried out in essentially the same way as the one for Theorem 1 of [4].

**Example 1:** A SCAD instance \( S_1 \) is defined such that
\[
S_1 = D_f \cup S_{ap} \cup S_{ax} \cup S_{una} \cup S_{scad}
\]
where
\[
S_{scad} = \{ prec(Ini, B), Lpre(F, B), Rpre(B, J), RpreL(F, J),
\]
\[
LpreL(F, M), preR(j, M), preM(Final), Tknss(Ini, S_0) = 2,
\]
\[
Tknss(B, S_0) = 0, Tknss(F, S_0) = 0, Tknss(J, S_0) = 0,
\]
\[
Tknss(J, S_0) = 0, Tknss(J, S_0) = 0,
\]
\[
Tknss(M, S_0) = 0, Tknss(Final, S_0) = 0
\]

Figure 1 is its pictorial presentation. Now a reachability problem can be stated as a SCAD entailment problem:
\[
S_1 \models \exists s. exec(s) \land (S_0 \sqsubseteq s) \land Tknss(Final, s) \geq 1?
\]
That is, is there a sequence of executable actions such that at least one token is delivered to the Final node? Define \( \overline{a} = \{ fire(Ini), fireB_1(B), fire(F), Fire(M) \} \), it can be seen that, let \( s_a = do(\overline{a}, S_0) \),
\[
S_1 \models exec(s_a) \land (S_0 \sqsubseteq s_a) \land Tknss(Final, s_a) = 1.
\]
From the fourth foundational axioms, it is obvious that \( S_0 \sqsubseteq s_a \). The executability of \( \overline{a} \) and \( Tknss(Final, s_a) = 1 \) can be verified by sequentially applying the four precondition axioms in \( S_{ap} \) and the three successor state axioms in \( S_{scad} \).

For example, \( Poss(\{ fire(Ini), S_0 \} , together with \( exec(S_0) \),
leads to \( exec(\{ do(fire(Ini)), S_0 \} ) \); whereas
\[
Tknss(Ini, do(fire(Ini), S_0)) = 1 \) and
\[
Tknss(B, do(fire(Ini), S_0)) = 1.
\]
Now, let
\[
b = \{ fire(Ini), fire(B), fireB_1(B), fire(F), Fire(J), Fire(M), Fire(M), Fire(M) \}
\]
It is obvious that \( Tknss(Final, s_b) = 2 \).

The K-boundedness of \( S_1 \), meanwhile, can be stated as a SCAD entailment problem in the form:
\[
S_1 \models exec(s) \land Tknss(p, s) \leq 2?
\]
The proof is based on the observation that all executable sequences are with finite length.

**VI. Summary**

In this paper, a graph-theoretic specification for the structural properties of activity diagrams, with adoptions of the concept of tokens in Petri-nets to model the dynamics these diagrams, is proposed. A second-order axiomatization of this semantics of UML activity diagrams called SCAD is further provided. The design of SCAD makes use of the strong correspondence between the situation in situation calculus, which is a sequence of actions starting from the initial state \( S_0 \), and the marking \( M \) in activity diagrams, which is resulted from a sequence of node firings starting from the firing of the initial node at initial marking.
